SUBMITTED 1 July 2019 REVISED 23 August 2019 ACCEPTED 17 December 2019

**ABSTRACT** Black soybean [*Glycine max* (L.) Merr.] produces isoflavones as secondary metabolites, which have many benefits for human health and plant defense system. Expression profiling can guide potential work in functional genomics of the isoflavone biosynthesis pathway. Previous studies showed the vital role of the *CHS8*, *CHI1A*, and *IFS2* genes in isoflavone biosynthesis. However, expression profiling of these genes in the local black soybean varieties is still limited. This study investigated the gene expression levels of the *CHS8*, *CHI1A*, *IFS2*, and *CHR* genes in local varieties, namely, UP106 (high isoflavone) and UP122 (low isoflavone) and its progenies, i.e., UP106xUP122 and UP122xUP106. Relative gene expression profiling was conducted on the basis of Reverse Transcriptase Polymerase Chain Reaction (RT-PCR) with *ACT2/7* as a housekeeping gene. As a result, the expression level of *CHS8* in UP122 was lower than that in UP106. No significant difference in the expression level of *CHI1A* was observed in all samples. The expression levels of *CHS8* and *CHI1A* in both progenies were higher than that in the parental line, whereas the expression levels of *IFS2* in both progenies were lower than that in the parental line. *CHS8* and *IFS2* expression from UP106xUP122 was higher than that from UP122xUP106, whereas *CHI1A* expression from UP122xUP106 was higher than that from UP106xUP122. *CHR* showed a high expression in the reciprocal cross; however, this expression did not exceed from UP106. In conclusion, the crossing between parental lines did not affect the gene expression level in the isoflavone biosynthesis pathway.

**KEYWORDS** black soybeans; isoflavone; local varieties; biosynthesis pathway; reverse transcriptase PCR

### 1. Introduction

Black soybeans contain carbohydrates, lipids, and a high protein content, which reaches approximately 70%, as well as vitamins and minerals (Dajanta et al. 2013; Lam et al. 2010). In Indonesia, black soybeans have contributed significantly to the food industry, e.g., as the raw material for the soy sauce industry. In various countries, such as China, Japan, and Korea, black soybeans have also been used as a drug for hundreds of years to detox, prevent inflammation, and improve the quality of red blood cells (Xu and Chang 2008).

Black soybeans are known as a plant that has isoflavone levels 100 times higher than other legumes (Xu and Chang 2008). Isoflavones have an essential role in the defense system against biotic and abiotic stresses and in the process of forming root nodules as a result of the interaction between soybean plants and microbes (Akada et al. 1993; Christie et al. 1996). In fact, isoflavones provide many benefits for human health, such as reducing the risk of cardiovascular disease, osteoporosis, menopausal

disorders, and cancer (Dhaubhadel 2011; Dixon 2004).

Many researchers have investigated the isoflavone biosynthesis pathway, which is constructed by a variety of enzymatic reactions. The enzymes involved in isoflavone biosynthesis are genetically encoded through the transcription and translation processes. Isoflavonoids are synthesized through the phenylpropanoid pathway. The precursor of the synthesis is L-phenylalanine. First, the amine group of L-phenylalanine is released. Then, cinnamic acid is produced through the Phenylalanine Ammonia-Lyase (PAL) enzyme activity. In the subsequent phase reaction, cinnamate 4-hydroxylase and 4-coumarate CoA ligase convert cinnamic acid into p-coumaroyl CoA (Dhaubhadel 2011). Previous studies showed that *CHR*, *CHI1A*, and *IFS2* are genes that play an important role in isoflavone biosynthesis (Yu et al. 2003). *CHR* and *CHI1A* are specific genes that are only found in legume plants. *CHR* gene expression plays a role in determining the composition ratio of isoflavones (daidzein/genistein/glycitein). Increased gene expression of *CHR* can increase the produc-

tion of the isoflavone daidzein (Yu et al. 2003). *CHI1A* expression plays an important role in the synthesis of type II chalcone isomerase that functions at the branching point between the production of flavonoids and isoflavonoids. *IFS* gene is one of the key genes in the synthesis of isoflavones. Previous research showed that the insertion of soybean *IFS* gene into nonlegume crops successfully alter the metabolism of nonlegume crops to produce the isoflavones genistein and daidzein (Jung et al. 2000).

The expression of genes related to the synthesis of isoflavones provides important information on the process of metabolic engineering of isoflavone in plants. However, information on gene expression profiles is still limited because the expression of isoflavone genes is strongly influenced by cultivar and geographical environment (Cheng et al. 2016). Thus, to manipulate the metabolism of isoflavones in Indonesian black soybean, research on the expression of genes related to the synthesis of isoflavones in black soybean needs to be conducted. The expression profiles of genes related to the synthesis of isoflavones can be used to determine the function of genomic information in the isoflavone biosynthesis pathway (Dhaubhadel et al. 2007). This research was conducted to analyze the gene expression profiles of *CHS*, *CHR*, *CHI1A*, and *IFS2* in the seeds of two local varieties of black soybeans (i.e., UP106 and UP122) and its crossbreeding result at the F4 generation using Reverse Transcriptase-Polymerase Chain Reaction (RT-PCR).

## 2. Materials and Methods

### 2.1. Plant and seed samples

The black soybean (*Glycine max* L. Merr) seeds used were local varieties, i.e., UP106 and UP122 obtained from the Laboratory of Plant Breeding, Faculty of Agriculture, Padjadjaran University (through Dr. Agung Karuniawan) and eight F4 genotypes as crossbreeding result. Plants were grown in the area of Tanjungsari, Sumedang (864 m above sea level) in February 2019. Pods were harvested when the plant has reached the R5 phase because isoflavone accumulation in soybeans occurs during the seed maturation stage (Dhaubhadel 2011). Pods were collected, cleaned, and drained, wrapped using aluminum foil with the label, frozen in liquid nitrogen, and stored in  $-80^{\circ}\text{C}$ .

### 2.2. Phenotypic measurement

In this study, phenotypic variables were measured and used as supporting data. The phenotypic variables included plant height, number of branches, number of pods per plant, number of seeds per plant, the weight of seeds per plant, and the weight of 100 grains.

### 2.3. RNA isolation and quantitative and qualitative analyses

Total RNA samples of black soybean seeds were isolated following the protocol of GeneJET Plant RNA Purification Mini Kit (Thermo Fisher Scientific™). RNA was an-

alyzed using electrophoresis and spectrophotometry to determine the quality and quantity.

### 2.4. cDNA synthesis

Approximately one  $\mu\text{g}$  of RNA was used for cDNA synthesis following the protocol of GoScript™ Reverse Transcriptase (Promega Corporation).

### 2.5. Reverse transcriptase PCR and data analysis

The primer sequences used for *CHS8*, *CHI1A*, *IFS2*, and *CHR* were obtained from a previous study (Gutierrez-Gonzalez et al. 2010), with *ACT2/7* as a housekeeping gene. The cDNA samples were amplified using the PCR reagent of the DreamTaq Green PCR Master Mix Kit (Thermo Fisher Scientific™) and the DNA engine thermal cycler Veriti™ 96-Well Thermal Cycler (Thermo Fisher Scientific™). PCR mixtures were prepared using 1  $\mu\text{L}$  cDNA, 0.5  $\mu\text{L}$  forward and reverse primers, 5  $\mu\text{L}$  DreamTaq Green PCR Master Mix, and up to 10  $\mu\text{L}$  nuclease-free water. PCR products were visualized in 2% agarose gel stained with FloroSafe DNA Stain. Electrophoresis products were visualized by the Gel Doc™ EZ Imager. The thickness of the bands obtained from agarose gel electrophoresis visualization was semiquantitatively analyzed using the ImageJ software (Sheffield 2008). Then, the expression values were tested using one-way analysis of variance (F3,8,  $p < 0.001$ ) with IBM SPSS20 software.

## 3. Results and Discussion

### 3.1. Phenotypic profile

Parental lines and their offspring showed variations in phenotypic profiles, except for plant height. In terms of plant height, all lines were nearly the same (Figure 3). However, the F4(122x106)e strain was higher than the two parental lines.

Variations in phenotypic profiles (Figure 1 and 2) can be observed from the numbers of pods and seeds per plant (Figure 4), seed weight per plant, and weight of 100 seeds (Figure 5). The two parental strains showed nearly the same numbers of pods and seeds per plant. The cross line generation showed higher numbers of pods and seeds per plant than the two parental lines, except for the F4(122x106)e line. Variations in seed weight per plant and weight of 100 seeds were observed among the lines. The cross line generation showed heavier seed weight per plant and weight of 100 seeds than the two parental lines, except for the F4(122x106)e line.

Based on the yield character, most of the offspring generations showed better yield than the two parental lines. This finding indicates that the yield character exhibited transgressive segregation. The F4(122x106)e line showed the best yield.

FIGURE 1 Phenotypic profile of parental lines (UP106 and UP122).

FIGURE 2 Phenotypic profile of offspring lines ((A49-B21 = F4(106x122)a; C19-D5 = F4(106x122)b; E5-F54 = F4(122x106)d; G19-H14 = F4(122x106)e).

### 3.2. Genes expression profile

#### 3.2.1 Relative expression of *CHS8* gene

The total relative gene expression shown in Figure 6 indicated that the four samples affected the relative gene expression level of *CHS8* ( $p$ -value < 0.05). UP106xUP122 and UP122xUP106 exhibited significant differences in *CHS8* relative gene expression in the isoflavone biosynthesis pathway. The *CHS* gene was expressed higher at the initial development stage of the seed, i.e., during the R5 phase, than that at the other stages (Fritze et al. 1991). The results showed a difference in the relative gene expression level of *CHS* in the four samples because of the differences in the enhancer elements of the *CHS* gene promoter, which could increase gene expression. Transcription factors that bind to different enhancer elements produced different *CHS* gene expression levels (Fritze et al. 1991).

#### 3.2.2 Relative expression of *CHI1A* gene

The *CHI1A* gene expression level was not significant in the four samples ( $p$ -value > 0.05). The highest expression levels were exhibited by UP106xUP122, UP106, UP122xUP106, and UP122. UP106xUP122 and UP122xUP106 did not exhibit a significant difference; thus, the reciprocal F4 generation had the same potential in expressing the *CHI1A* gene. Consistent with the findings of Gutierrez-Gonzalez et al. (2010), we observed that *CHI1A* gene expression was not significant in the four samples. Moreover, the *CHI1A* gene showed stable expression levels during the generative growth phases, i.e., R5–R7, indicating that *CHI* ensures the stable synthesis of liquiritigenin and naringenin in all four genotypes.

#### 3.2.3 Relative expression of *IFS2* gene

*IFS2* showed differential expression in the four samples ( $p$ -value < 0.05). The *IFS2* gene expression levels exhibited by UP106xUP122 and UP122xUP106 were higher than those by the two parents. Thus, both UP106xUP122 and UP122xUP106 crosses exhibited significant differences, which, in this case, the group of tillers resulting from the crossing of UP106xUP122 had a higher poten-

tial level of relative gene expression than the group of offspring resulting from the crossing of UP122xUP106.

#### 3.2.4 Relative expression of *CHR* gene

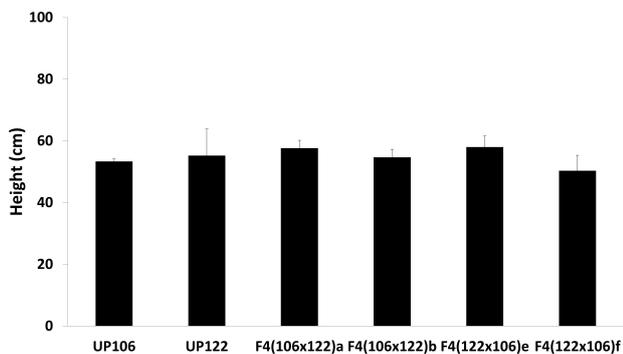

*CHR* showed the highest ratio in UP106, UP106xUP122, UP122xUP106, and UP122. The ratios in UP106xUP122 and UP122xUP106 were higher than that in UP122 but did not exceed that in UP106. The crossing of UP106xUP122 and UP122xUP106 had a significant effect ( $p$ -value < 0.05) on the *CHR* gene expression level. Moreover, UP106xUP122 had a higher potential level of relative gene expression than the reciprocal UP122xUP106.

Particularly for legume plants, the chalcone reductase enzyme encoded by the *CHR* gene is needed for the production of chalcone isoliquiritigenin. The *CHR* enzyme will compete with the *CHI* enzyme as a determinant of the relative changes in total genistein and daidzein formed by the division of the intermediate pathway from genistein to the branch of daidzein through increased *CHR* activity (Gutierrez-Gonzalez et al. 2010).

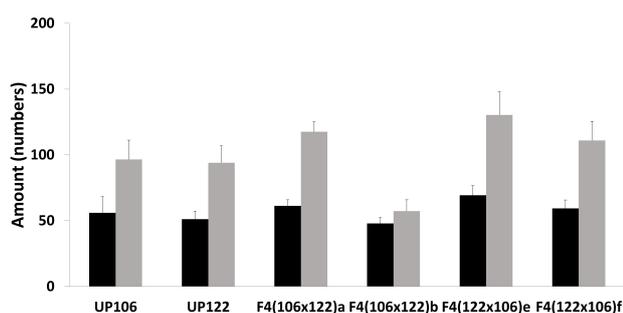

#### 3.2.5 Summary of Genes Expression Profile

The overall profile of relative gene expression in *CHS8*, *CHI1A*, *IFS2*, and *CHR* showed a positive correlation between parents and its F4 generation. The F4 generation UP106xUP122 has a higher potential for gene expression than its reciprocal because UP106 that acts as the female parent in the cross has a higher potential for gene expression than UP122. By contrast, the F4 generation UP122xUP106 has a lower potential for gene expression than its reciprocal because UP122 that acts as the female parent in the cross has a lower potential for gene expression than UP106.

Genetic variation formed in the F4 generation, resulted from the crossing UP106xUP122, was caused by genetic recombination between the parents. Genetic recombination is the exchange of genetic material between individuals reproduced sexually that produce recombinant offspring in segregation generation. Genetic recombination occurs through a cellular process during meiosis known as crossing over (Acquaah 2012).

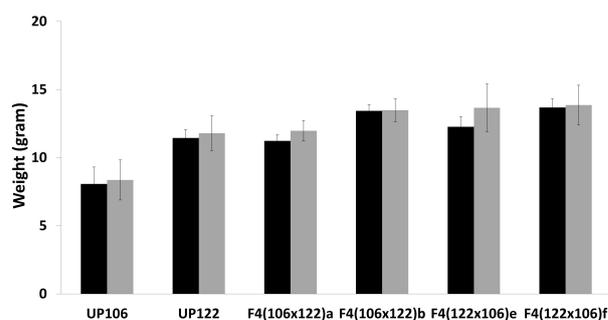

**FIGURE 3** Plant height of black soybean of parental lines (UP106 and UP122) and cross lines (F4(106x122)a; F4(106x122)b; F4(122x106)e; F4(122x106)f). Bars showed the height in cm with triplicates measurement and standar deviation.

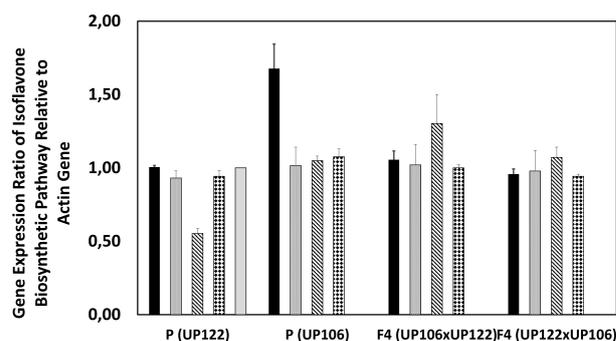

**FIGURE 4** Pod (Black Bar) and seed (Grey Bar) numbers per plant of parental (UP106 and UP122) and crossing lines (F4(106x122)a; F4(106x122)b; F4(122x106)e; F4(122x106)f). Bars showed the triplicates measurement and standar deviation.

Crossing over is the exchange of genetic material between homologous chromosomes that produce recombinant chromosomes in sexual reproduction, and this event is one of the final stages of genetic recombination that occurs in the pachytene prophase I stage of meiosis in synapctic processes. When chromosomal crossover occurs, homologous chromosomes pair up with each other and exchange segments of their respective genetic material to form recombinant chromosomes. Chromosomal crossover is an essential part of the normal chromosome segregation process that occurs during meiosis (Snustad and Simmons 2012).

The F4 generation has a complex and diverse mix of traits. Variations in cytoplasmic genomes can affect the yield character of the F4 generation phenotype (Park et al. 2006; Zeyl et al. 2005). Genetic variations in the cytoplasm and nucleus affect the interactions that control genetic variation in the F4 generation, which is the result of different combinations of its parents, *i.e.*, UP106xUP122 and its reciprocal UP122xUP106 (Juenger et al. 2010; McKay et al. 2003). According to Chiari et al. (2006), the effect of variations in the cytoplasm needs to be considered in inheritance studies because it will affect the contribution of parental lines to their offspring. Six types of isoflavones show the presence of cytoplasmic effects (Chiari et al. 2006).

**FIGURE 5** Seed weight per plant (Black bar) and weight of 100 seeds (Grey bar) of parental (UP106 and UP122) and crossing lines (F4(106x122)a; F4(106x122)b; F4(122x106)e; F4(122x106)f). Bars showed the triplicates measurement and standar deviation.

**FIGURE 6** Relative Expression Value based on Semi-quantitative Analysis of Reverse Transcriptase PCR. Genes are CHS8 (Black Bar), CHI1A (Dotted Bar), IFS2 (Stripes Bar), CHR (Diamond Bar), F6H3 (Grey Bar), respectively. Bars showed the triplicates measurement and standar deviation.

Each genotype group produces different gene expression levels in *CHS8*, *CHI1A*, *IFS2*, *CHR*, and *F6H3*, (Figure 6). Differential expression can be attributed to the regulation of gene expression at the transcription level of each genotype. Cheng et al. (2016) showed that the genotypes were the most critical factors in determining the form and content of isoflavones. Each genotype has a different genetic variation (polymorphism) because of the presence of single-nucleotide polymorphisms (SNPs) that distinguish the genetic information of one individual from that of another individual. SNPs have an influence on the gene expression level (Stranger et al. 2007; Veyrieras et al. 2008). SNPs on the alleles of each genotype will cause an allelic-specific expression, in which two alleles are different or more genes are expressed at different levels. Mutations cause changes in the regulatory element (there is at least one regulator mutation) that appears in cis-acting regions (Marioni et al. 2008). Transcriptional regulatory elements in cis-acting regions contain recognition sites where transcription factors attach as trans-acting elements, which enhance or suppress transcription (Maston et al. 2006).

#### 4. Conclusions

In conclusion, *CHS8*, *CHI1A*, and *IFS2* showed differential expression in the parental lines and reciprocal F4

hybrids. UP106 (high isoflavone) showed higher expression of *CHS8* than UP122 (low isoflavone). By contrast, UP122 (low isoflavone) showed higher expression of *IFS2* than UP106 (high isoflavone). The crossing between parental lines did not affect the gene expression level.
